Visitors

Installation & configuration

Installation:

opam update opam install visitors

To configure ocambuild, add this in _tags:

```
true: \
  package(visitors.ppx), \
  package(visitors.runtime)
```

To configure Merlin, add this in .merlin:

PKG visitors.ppx PKG visitors.runtime

Annotating a type definition with [@@deriving visitors { ... }]...

```
type expr =

                                               int is inherited
        self#visit EConst env c0
    | EAdd (c0, c1) ->
        self#visit EAdd env c0 c1
end
```

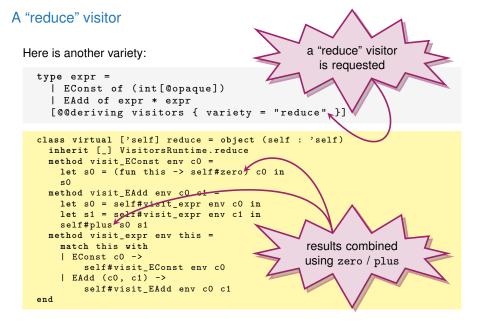

A "map" visitor a "map" visitor There are several varieties of visitors: is requested type expr = | EConst of int | EAdd of expr * expr [@@deriving visitors { variety = "map"_}] class virtual ['self] map = object (self : 'self) inherit [] VisitorsRuntime.map method visit EConst env c0 = let r0 = self#visit int env c0 in EConst r0 ← method visit EAdd env c0 c1 = let r0 = self#visit_expr env e0 in let r1 = self#visit expr env c1 in EAdd (r0, r1) 🗲 method visit_expr env this = default behavior match this with | EConst c0 -> is to rebuild a tree self#visit EConst env c0 | EAdd (c0, c1) -> self#visit_EAdd env c0 c1 end

Using a "map" visitor

Inherit a visitor class and override one or more methods:

```
let add e1 e2 = (* A smart constructor. *)
match e1, e2 with
| EConst 0, e
| e, EConst 0 -> e
| _, _ -> EAdd (e1, e2)
let optimize : expr -> expr =
let v = object (self)
inherit [_] map
method! visit_EAdd env e1 e2 =
add
        (self#visit_expr env e1)
        (self#visit_expr env e2)
end in
v # visit_expr ()
```

This addition-optimization pass is **unchanged** if more expression forms are added.

A "reduce" visitor

Here is another variety:

```
type expr =
  | EConst of (int[@opaque] 🗡
  | EAdd of expr * expr
  [@@deriving visitors { variety = "reduce" }]
class virtual ['self] reduce = object (self :
                                              'self)
  inherit [] VisitorsRuntime.reduce
  method visit EConst env c0 =
   let s0 = (fun this -> self#zero c0 in
    s0
  method visit EAdd env c0 c1 =
   let s0 = self#visit expr env c0 in
   let s1 = self#visit_expr env c1 in
   self#plus s0 s1
  method visit_expr env this =
                                             @opaque subtrees
   match this with
    | EConst c0 ->
                                               are not visited
        self#visit_EConst env c0
    | EAdd (c0, c1) ->
        self#visit EAdd env c0 c1
end
```

A "reduce" visitor look Ma. Here is another variety: full type inference! type expr = EConst of (int[@opaque]) | EAdd of expr * expr [@@deriving visitors { variety = "reduce" }] class virtual ['selff reduce = object (self : 'self) inherit [] VisitorsRuntime.reduce method visit EConst env c0 = let s0 = (fun this -> self#zero) c0 in s0 method visit EAdd env c0 c1 = let s0 = self#visit expr env c0 in let s1 = self#visit_expr env c1 in self#plus s0 s1 method visit expr env this = class is polymorphic match this with | EConst c0 -> in env and monoid self#visit_EConst env c0 | EAdd (c0, c1) -> self#visit EAdd env c0 c1 end

Inherit the visitor, inherit a monoid, override one or more methods:

```
let size : expr -> int =
  let v = object
    inherit [_] reduce as super
    inherit [_] VisitorsRuntime.addition_monoid
    method! visit_expr env e =
        1 + super # visit_expr env e
end in
    v # visit_expr ()
```

This size computation remains **unchanged** if more expression forms are added.

What we have seen so far

- Several built-in varieties: iter, map, endo, reduce, mapreduce, fold
- Arity two, too: iter2, map2, reduce2, mapreduce2, fold2
- Monomorphic visitor methods, polymorphic visitor classes
- All types inferred

Support for parameterized data types

We wish to traverse parameterized data types, too.

But: how does one traverse a subtree of type 'a?

Two approaches are supported:

- declare a virtual visitor method visit_'a
 - 'a is treated as a fixed/unknown type, not really as a parameter
- pass a function visit_'a to every visitor method.
 - allows / requires methods to be polymorphic in 'a
 - more compositional

In this talk: monomorphic generated methods, polymorphic hand-written methods.

A visitor for a parameterized type

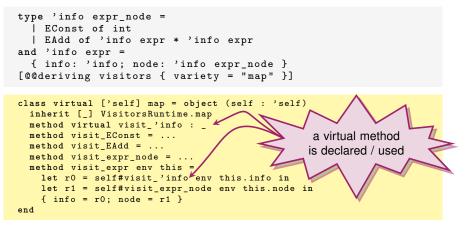

Here is a "monomorphic-method" visitor for a parameterized type:

```
type 'info expr node =
  | EConst of int
  | EAdd of 'info expr * 'info expr
and 'info expr =
 { info: 'info; node: 'info expr_node }
[@@deriving visitors { variety = "map" }]
class virtual ['self] map = object (self : 'self)
 inherit [ ] VisitorsRuntime.map
 method virtual visit 'info :
 method visit_EConst = ...
 method visit EAdd = ...
 method visit expr node = ...
 method visit_expr env this =
   let r0 = self#visit 'info env this.info in
   let r1 = self#visit_expr_node env this.node in
   \{ info = r0; node = r1 \}
end
```

The type of visit_'info is 'env -> 'info1 -> 'info2.

A visitor for a parameterized type

Here is a "monomorphic-method" visitor for a parameterized type:

The type of visit_'info is 'env -> 'info1 -> 'info2.

Using a visitor for a parameterized type

This visitor can map **undecorated** expressions to **decorated** expressions:

```
let number (e : _ expr) : int expr =
  let v = object
    inherit [_] map
    val mutable count = 0
    method visit_'info _env _info =
        let c = count in count <- c + 1; c
end in
    v # visit_expr () e</pre>
```

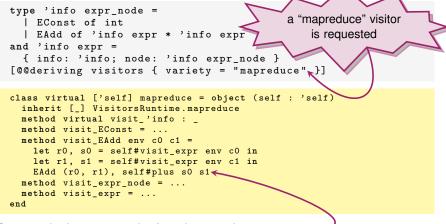

and vice-versa:

```
let strip (e : _ expr) : unit expr =
  let v = object
    inherit [_] map
    method visit_'info _env _info = ()
  end in
    v # visit_expr () e
```

The visitor class is **polymorphic** in 'env, 'info1 and 'info2.

A "mapreduce" visitor for a parameterized type

Here is another variety of visitor for this parameterized type:

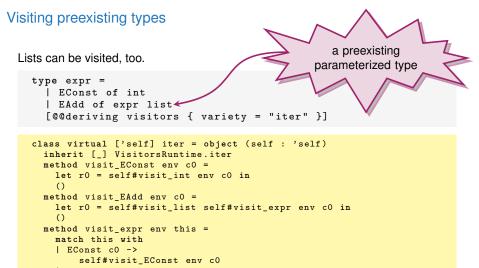

Every method returns a **pair** of a subtree and a summary.

Using a visitor for a parameterized type

This visitor can **annotate** every subexpression with its size:

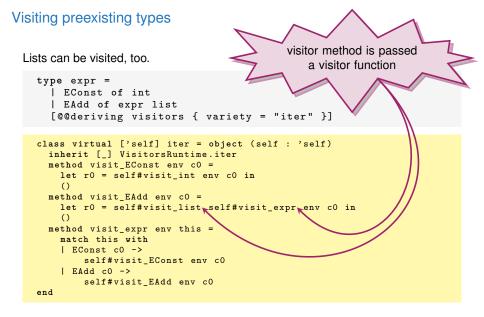

```
let annotate (e : _ expr) : int expr =
let v = object
inherit [_] mapreduce as super
inherit [_] VisitorsRuntime.addition_monoid
method! visit_expr env { info = _; node } =
let node, size = super#visit_expr_node env node in
let size = size + 1 in
{ info = size; node }, size
method visit_'info _env _info =
assert false (* never called *)
end in
let e, _ = v # visit_expr () e in
e
```

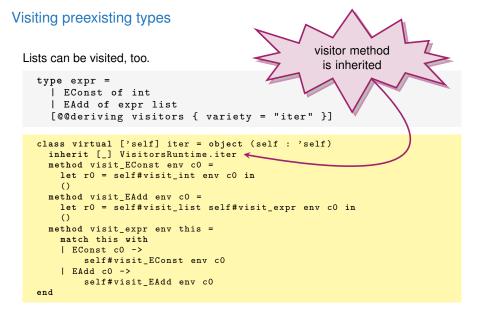

```
| EAdd c0 ->
```

self#visit_EAdd env c0

end

Predefined visitor methods

The class VisitorsRuntime.map offers this method:

```
class ['self] map = object (self)
 (* One of many predefined methods: *)
 method private visit_list: 'env 'a 'b .
   ('env -> 'a -> 'b) -> 'env -> 'a list -> 'b list
   = fun f env xs ->
      match xs with
   | [] ->
      []
   | x :: xs ->
      let x = f env x in
      x :: self # visit_list f env xs
end
```

This method is **polymorphic**, so multiple instances of list are not a problem.

Although they follow fixed patterns, visitors are quite versatile.

They are like higher-order functions, only more **customizable** and **composable**. More fun with visitors:

- visitors for open data types and their fixed points (link);
- visitors for hash-consed data structures (link);
- iterators out of visitors (link).

In the remainder of this talk:

Can we traverse abstract syntax with binding?

Visitors Unchained

Can a visitor traverse abstract syntax with binding constructs?

Can a visitor traverse **abstract syntax with binding** constructs? Can this be done in a **modular** way?

Can a visitor traverse abstract syntax with binding constructs?

Can this be done in a modular way?

Exactly which separation of concerns should one enforce?

Can a visitor traverse abstract syntax with binding constructs?

Can this be done in a modular way?

Exactly which separation of concerns should one enforce?

- There are many binding constructs,
 - there are even combinator languages for describing binding structure!
- and many common operations on terms,
 - often specific of one representation of names and binders,
 - sometimes specific of two such representations, e.g., conversions.
- Can we insulate the end user from this complexity?

We suggest distinguishing three principals...

The end user

Desiderata

The end user wishes:

- to describe the structure of ASTs in a concise and declarative style,
- not to be bothered with implementation details,
- possibly to have access to several representations of names,
- to get access to a toolkit of ready-made operations on terms.

Example: abstract syntax of the λ -calculus

Let the type ('bn, 'term) abs be a synonym for 'bn * 'term. The end user defines his syntax as follows:

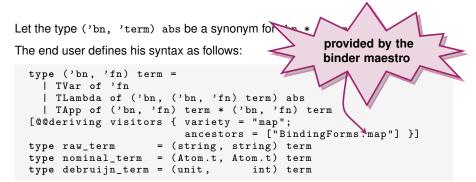

He gets multiple representations of names.

At least two are used in any single application. (Parsing. Printing.)

He gets **visitors** for free. The method visit_abs is used at abstractions.

iter, map, iter2 needed in practice. Focusing on map in this talk.

Example: abstract syntax of the λ -calculus

He gets multiple representations of names.

At least two are used in any single application. (Parsing. Printing.)

He gets visitors for free. The method visit_abs is used at abstractions.

iter, map, iter2 needed in practice. Focusing on map in this talk.

The binder maestro

An easy job?

Implementing visit_abs is the task of our sophisticated binder maestro. The key is to extend the environment when entering the scope of a binder. Easy?

An easy job?

Implementing visit_abs is the task of our sophisticated binder maestro.

The key is to extend the environment when entering the scope of a binder.

Easy? Maybe — yet, the binder maestro:

- does not know what operation is being performed,
- does not know what representation(s) of names are in use,
- therefore does not know the types of names and environments,
- let alone how to extend the environment.

What he knows is where and with what names to extend the environment.

A convention

The binder maestro agrees on a **deal** with the operations specialist.

"I tell you when to extend the environment; you do the dirty work."

The binder maestro calls a method which the operations specialist provides:

```
(* A hook that defines how to extend the environment. *)
method private virtual extend: 'env -> 'bn1 -> 'env * 'bn2
```

This is a bare-bones API for describing binding constructs.

The class BindingForms.map offers the method visit_abs:

```
class virtual ['self] map = object (self : 'self)
 (* A visitor method for the type abs. *)
 method private visit_abs: 'term1 'term2 . _ ->
  ('env -> 'term1 -> 'term2) ->
  'env -> ('bn1, 'term1) abs -> ('bn2, 'term2) abs
 = fun _ visit_'term env (x1, t1) ->
    let env, x2 = self#extend env x1 in
    let t2 = visit_'term env t1 in
    x2, t2
 (* A hook that defines how to extend the environment. *)
 method private virtual extend: 'env -> 'bn1 -> 'env * 'bn2
end
```

This method:

The class BindingForms.map offers the method visit_abs:

```
class virtual ['self] map = object (self : 'self)
 (* A visitor method for the type abs. *)
 method private visit_abs: 'term1 'term2 . _ ->
  ('env -> 'term1 -> 'term2) ->
  'env -> ('bn1, 'term1) abs > ('bn2, 'term2) abs
= fun _ visit_'term env (x1, t1) ->
    let env, x2 = self#extend env x1 in
    let t2 = visit_'term env t1 in
    x2, t2
  (* A hook that defines how to extend the environment. *)
  method private virtual extend: 'env -> 'bn1 -> 'env * 'bn2
end
```

This method:

takes a visitor function for terms, an environment,

The class BindingForms.map offers the method visit_abs:

```
class virtual ['self] map = object (self : 'self)
 (* A visitor method for the type abs. *)
 method private visit_abs: 'term1 'term2 . _ ->
  ('env -> 'term1 -> 'term2) ->
  'env -> ('bn1, 'term1) abs -> ('bn2, 'term2) abs
 = fun _ visit_'term env (x1, t1) ->
    let env x2 = self#extend env x1 in
    let t2 = visit_'term env t1 in
    x2, t2
 (* A hook that defines how to extend the environment. *)
 method private virtual extend: 'env -> 'bn1 -> 'env * 'bn2
end
```

This method:

takes a visitor function for terms, an environment, -

The class BindingForms.map offers the method visit_abs:

```
class virtual ['self] map = object (self : 'self)
 (* A visitor method for the type abs. *)
 method private visit_abs: 'term1 'term2 . _ ->
  ('env -> 'term1 -> 'term2) ->
  'env -> ('bn1, 'term1) abs -> ('bn2, 'term2) abs
= fun _ visit_'term env (x1, 1) ->
   let env, x2 = self#extend env x1 in
   let t2 = visit_'term env t1 in
   x2, t2
 (* A hook that defines how to extend the environment. *)
 method private virtual extend: 'env -> 'bn1 -> 'env * 'bn2
end
```

This method:

- takes a visitor function for terms, an environment,
- an abstraction, i.e., a pair of a name and a term, and

The class BindingForms.map offers the method visit_abs:

```
class virtual ['self] map = object (self : 'self)
 (* A visitor method for the type abs. *)
 method private visit_abs: 'term1 'term2 . _ ->
  ('env -> 'term1 -> 'term2) ->
  'env -> ('bn1, 'term1) abs -> ('bn2, 'term2) abs
 = fun _ visit_'term env (x1, t1) ->
    let env, x2 = self#extend env x1 in
    let t2 = visit_'term env t1 in
    x2, t2
 (* A hook that defines how to extend the environment. *)
 method private virtual extend: 'env -> 'bn1 -> 'env * 'bn2
end
```

This method:

- takes a visitor function for terms, an environment,
- an abstraction, i.e., a pair of a name and a term, and
- returns a pair of a transformed name and a transformed term. -

That's all there is to single-name abstractions.

More binding constructs later on...

For now, let's turn to the final participant.

The operations specialist

A toolbox of operations

There are many operations on terms that the end user might wish for:

- testing terms for equality up to α-equivalence,
- finding out which names are free or bound in a term,
- applying a renaming or a substitution to a term,
- converting a term from one representation to another,
- (plus application-specific operations.)

To implement one operation, the specialist decides:

- the types of names and environments,
- what to do at a free name occurrence,
- how to extend the environment when entering the scope of a bound name.

As an example, let's implement import, which converts raw terms to nominal terms.

1. An import environment maps strings to atoms:

```
module StringMap = Map.Make(String)
type env = Atom.t StringMap.t
let empty : env = StringMap.empty
```

```
2. When the scope of x is entered,
```

the environment is extended with a mapping of the string x to a fresh atom a.

```
let extend (env : env) (x : string) : env * Atom.t =
  let a = Atom.fresh x in
  let env = StringMap.add x a env in
  env, a
```

(An atom carries a unique integer identity.)

This is true regardless of which binding constructs are traversed.

3. When an occurrence of the string *x* is found, the environment is looked up so as to find the corresponding atom.

```
exception Unbound of string
let lookup (env : env) (x : string) : Atom.t =
  try StringMap.find x env
  with Not_found -> raise (Unbound x)
```

The previous instructions are grouped in a little class — a "kit":

```
class ['self] map = object (_ : 'self)
  method private extend = extend
  method private visit_'fn = lookup
end
```

This is KitImport.map.

That's all there is to it... but...

The end user must **work** a little bit to **glue** everything together...

The end user must **work** a little bit to **glue** everything together...

... and may feel slightly annoyed.

Typical glue

For one operation, the end user must write 5 lines of glue code:

For 15 operations, this hurts.

Functors can help in simple cases, but are not flexible enough.

Macros help, but are ugly. Is there a better way?

Towards advanced binding constructs

There are many binding constructs out there.

"let", "let rec", patterns, telescopes, ...

We have seen how to **programmatically** define a binding construct. Can it be done in a more **declarative** manner?

A domain-specific language

Here is a little language of binding combinators:

t	=::		sums, products, free occurrences of names, etc.
		abstraction(p)	a pattern, with embedded subterms
p	::=		sums, products, etc.
		binder(x)	a binding occurrence of a name
		outer(t)	an embedded term
		rebind(p)	a pattern in the scope of any bound names on the left

Inspired by C α ml (F.P., 2005) and Unbound (Weirich et al., 2011).

A domain-specific language

Here is a little language of binding combinators:

t	=::		sums, products, free occurrences of names, etc.
		abstraction(p)	a pattern, with embedded subterms
p	::= 	binder(x) outer(t) rebind(p) inner(t)	sums, products, etc. a binding occurrence of a name an embedded term a pattern in the scope of any bound names on the left — sugar for rebind(outer(t))

Inspired by C α ml (F.P., 2005) and Unbound (Weirich et al., 2011).

A domain-specific language

Here is a little language of binding combinators:

Inspired by C α ml (F.P., 2005) and Unbound (Weirich et al., 2011).

These primitive constructs are just annotations:

```
type 'p abstraction = 'p
type 'bn binder = 'bn
type 't outer = 't
type 'p rebind = 'p
```

Their presence triggers calls to appropriate (hand-written) visit_ methods.

While visiting a pattern, we keep track of:

- the outer environment, which existed outside this pattern;
- the current environment, extended with the bound names encountered so far.

Thus, while visiting a pattern, we use a richer type of contexts:

type 'env context = { outer: 'env; current: 'env ref }

- Not every visitor method need have the same type of environments!

With this in mind, the implementation of the visit_ methods is straightforward...

This code takes place in a map visitor:

```
class virtual ['self] map = object (self : 'self)
  method private virtual extend: 'env -> 'bn1 -> 'env * 'bn2
  (* The four visitor methods are inserted here... *)
end
```

1. At the root of an abstraction, a fresh context is allocated:

```
method private visit_abstraction: 'env 'p1 'p2 .
  ('env context -> 'p1 -> 'p2) ->
  'env -> 'p1 abstraction -> 'p2 abstraction
= fun visit_p env p1 ->
    visit_p { outer = env; current = ref env } p1
```

2. When a bound name is met, the current environment is extended:

```
method private visit_binder: _ ->
    'env context -> 'bn1 binder -> 'bn2 binder
= fun visit_'bn ctx x1 ->
    let env = !(ctx.current) in
    let env, x2 = self#extend env x1 in
    ctx.current := env;
    x2
```

3. When a term that is **not in the scope** of the abstraction is found, it is visited in the **outer** environment.

```
method private visit_outer: 'env 't1 't2 .
  ('env -> 't1 -> 't2) ->
  'env context -> 't1 outer -> 't2 outer
= fun visit_t ctx t1 ->
    visit_t ctx.outer t1
```

4. When a subpattern marked rebind is found, the current environment is installed as the outer environment.

```
method private visit_rebind: 'env 'p1 'p2 .
  ('env context -> 'p1 -> 'p2) ->
  'env context -> 'p1 rebind -> 'p2 rebind
= fun visit_p ctx p1 ->
    visit_p { ctx with outer = !(ctx.current) } p1
```

This affects the meaning of outer inside rebind.

Example use: telescopes

A dependently-typed λ -calculus whose Π and λ forms involve a telescope:

Conclusion

Conclusion

Visitors are powerful.

Visitor classes are partial, composable descriptions of operations.

Visitors can traverse abstract syntax with binding.

- Syntax, binding forms, operations can be separately described.
- Syntax and even binding forms can be described in a declarative style.
- Open-ended, customizable approach.

Limitations:

- Macros are ugly.
- No proofs.
- Some operations may not fit the visitor framework;
- Some binding forms do not easily fit in the low-level framework or in the higher-level DSL, e.g., Unbound's *Rec*.
